Meningiomas are estimated to constitute 13 to 26% of all intracranial tumors\(^1\). Most meningiomas are slow-growing, benign neoplasms, deriving from arachnoid cap cells, and are classified as grade I according to the World Health Organization histopathologic classification\(^2\). Atypical grade II meningiomas are reported in 5 to 7% of all cases, whereas the incidence of malignant grade III meningiomas affects 0.17 out of 100,000 people per year\(^3\).

Incidences of meningiomas increase with age and are most common in the sixth and seventh decade of life. In adults, there is a marked female bias. Meningiomas are predominantly found in the brain, most frequently in the parasagittal area\(^4\), and the cavernous sinus\(^5\). Spinal meningiomas account for less than 10% of all meningiomas and are most often situated in the thoracic spine\(^6\).

Most meningiomas have good long-term prognosis. In population-based cancer registry series of patients, the overall five year relative survival following diagnosis exceeds 80%\(^7\). The large majority of meningiomas can be cured by surgery\(^8\). The primary goal of surgery is complete removal of the tumor, limiting possible recurrence and increasing the chance for a cure. Because most meningiomas are histologically benign, a less than optimal functional outcome after treatment may not be acceptable.

Notwithstanding substantial improvements in microsurgical techniques, surgery of meningiomas has a high rate of significant complications, dependent on the location of the lesion\(^9\). Mortality rates are reportedly up to 10%\(^10\). These considerations motivate the application of single fraction stereotactic radiosurgery (SRS) and fractionated radiotherapy (SRT) as minimally invasive treatment options.

Small, spherically shaped meningiomas with a maximum dimension less than 3 mm are commonly selected for SRS, while SRT is usually employed for large, irregularly shaped lesions\(^12,17\). The radiobiologic benefits of dose fractionation allow the surrounding healthy tissue to recover from the large SRT doses\(^18\).

SRS and SRT should not be compared, since both modalities are used in different clinical scenarios and should be available to complement each other, providing safer treatment options for patients.

An overview of some dedicated studies of SRS and SRT treatments of benign meningiomas is presented in the table below. The treatment outcomes are expressed in terms of local control and tumor response, since slow-growing, benign meningiomas are notorious for prolonged intervals between treatment and tumor regression\(^13\). The tumor response can be quantified by comparing the gross tumor volume contrast-enhanced margins in the three standard MRI dimensions before and after treatment. The tumor response is in general defined as a measurable reduction of the tumor size in any dimension.

The mean prescribed SRS dose is situated between 14 and 16 Gy in order to minimize long-term toxicity while maintaining efficacy. This dose is typically delivered by multiple noncoplanar arcs using a set of conical collimators, ensuring steep dose fall-off in the close proximity of organs at risk.
The mean prescribed SRT dose ranges from 48 to 54 Gy, delivered in 26 to 30 daily fractions of 1.8 to 2 Gy. All SRT studies utilize a micro-multi-leaf collimator for field shaping, which enables versatile treatment delivery options like static conformal beams, dynamic conformal arcs and intensity-modulated radiotherapy.

The mean follow-up for the patients in the described studies ranges from 17 to 45 months. The tumor growth control rates for both SRS and SRT treatments are higher than 92% for all studies presented.

## Overview of the recent clinical literature on SRS and SRT for meningiomas

The tumor response can be quantified by comparing the gross tumor volume contrast-enhanced margins in the three standard MRI dimensions before and after treatment. A complete response is defined as the absence of contrast-enhancing tumor on follow-up MRI studies. For the majority of studies, a partial response is defined as a reduction of at least 50% in the largest tumor dimension.

A reduction of the tumor volume, defined as the tumor response, was observed in 30 to 70% of all cases. The treatment was well tolerated, with an incidence of late toxicity less than 9%.

It is therefore concluded that both SRS and SRT, delivered as primary treatment or adjuvant to conservative resection, have improved the management of intracranial benign meningiomas and are highly effective and safe treatment options.
